Cryotherapy is the application of cold as a therapeutic intervention,1-5 which has been used to facilitate recovery from an acute injury since the 1800s.6 Although cold can be applied to the body surface in a variety of ways, ice has been traditionally used to promote healing from injuries.¹ Cryotherapy modalities are also used to promote recovery between exercise training sessions and competitive events when some athletes experience delayed-onset muscle soreness (DOMS).² Despite the widespread use of cryotherapy, the findings of research on differing cryotherapy modes, temperatures, and treatment times are inconsistent. The purpose of this report is to review evidence pertaining to the effectiveness of cryotherapy for treatment of DOMS. Specifically, we review what is known about (a) systemic responses to cold application, (b) the possible benefits of cryotherapy for exercise recovery, (c) performance decrements associated with DOMS, and (d) methods used to measure recovery from DOMS.

Common modes of cryotherapy administration include cold water immersion (CWI; Table 1), ice massage (Table 2), ice pack application (Table 3), or the use of a cold sprays or gels. The use of cryotherapy as part of the widely-accepted Rest, Ice, Compression, Elevation (RICE) approach to sports injury management is often the first response to a musculoskeletal injury,²,³ but the optimal temperature and duration of treatment are not well-established. Various types of cold packs and cold sprays, which produce different levels of subcutaneous tissue cooling, are readily available, but confusion exists about the best practice for realization of optimal therapeutic benefit. CWI temperature and treatment duration are not universally accepted; researchers have reported CWI temperatures range from 50–60 °F and reported treatment times range from 5–20 minutes.⁵-⁷ A possible explanation for this inconsistency may be lack of a clear understanding of the physiologic effects of cryotherapy. The research evidence pertaining to the use cryotherapy as an injury recovery modality is mixed; some evidence supports its use,⁸-¹⁰ but other evidence fails to support the practice.¹¹-¹³ A lack of evidence-based recommendations for the use cryotherapy in treatment of DOMS presents clinicians with a decision-making dilemma that results in wide variation in practices.

**Systemic Responses to Cold Exposure**

Exposure to cold elicits multiple systemic responses, which relate to the potential benefits of cryotherapy treatment. Until the 1970s, the theorized positive effect of cold application was attributed to a decrease in blood flow that suppressed hemorrhage and edema formation.<sup>4</sup> Subsequently, Knight<sup>14</sup> introduced the secondary hypoxic injury theory, which suggested that a lack of oxygen at the injury site induces damage to the surrounding cells.<sup>14,15</sup> The positive effects of cryotherapy were related to a decrease in metabolism of the tissues in the vicinity of the injured tissues.<sup>4</sup> By lowering the tissue temperature, the cells’ demand for oxygen is also lowered, which makes them less likely to be damaged by oxygen deprivation.

Research has demonstrated that intramuscular temperature drops when cold is applied to the body surface, and it continues to drop after the cold modality has been removed.<sup>16-18</sup> Whole-body cold exposure increases levels of circulating thyroid hormones, which increases the basal metabolic rate. CWI sometimes involves submersion of a large portion of the body, which will elicit a systemic response.

**Cryotherapy Use in Acute Injury Management and Exercise Recovery**

Cryotherapy is often administered during the acute inflammation phase for reduction of pain and swelling.<sup>4</sup> Although pain and swelling are symptoms of inflammation, research findings suggest that suppression of other aspects of the inflammatory response may be detrimental to the healing process.<sup>19</sup> According to Knight,<sup>14</sup> decrease in secondary hypoxic injury, which may prevent subsequent swelling, is the primary benefit derived from cryotherapy.

Research has demonstrated that skin temperature remains lower than normal for several hours after prolonged cryotherapy, even after removal of the cold
modality. The cold skin stimulus generates afferent neural impulses that are conveyed by large, myelinated nerve fibers at a much faster velocity than that of pain impulses conveyed by smaller unmyelinated nerve fibers, which inhibits transmission of pain impulses within the spinal cord and which suppresses the stretch reflex. The subjective nature of pain sensations has made the analgesic effect of cryotherapy difficult to study.

Although cryotherapy use for acute injury treatment is strongly supported by research evidence, its effect on recovery from DOMS remains controversial. DOMS is typically associated with high-intensity eccentric muscle actions. Symptoms may include tenderness to touch and debilitating pain that may last up to 72 hours after exercise. Some researchers have suggested that CWI is more effective than hot/cold contrast baths or no treatment for reduction of pain and restoration of normal function, whereas others have reported that CWI increased muscle pain in the days following treatment.

**Performance Decrement in DOMS**

Substantial reduction in muscular strength and power has been documented after the onset of DOMS induced by eccentric muscle actions. The greatest reduction in strength and power occurs during the period from 24 to 48 hours postexercise. Treatment during this postexercise period may be crucial for athletes who compete in sports that involve competition over a period of several days or on consecutive days. If cryotherapy can mitigate DOMS, it could optimize performance during multiday sporting events. Whether or not cryotherapy actually has a physiologic effect on DOMS remains unclear.

**Measurement of Recovery From DOMS**

**Pain**

Although pain is a subjective sensation, its perception can inhibit performance. Pain related to DOMS may result from disruption of the contractile component of muscle tissue, especially at the Z-line of the sarcomere. A visual analog scale (VAS) quantifies pain perception by having the patient make a mark on a line that represents a continuum from no pain to excruciating pain. Athletes and nonathletes may differ in terms of tolerance for pain, which may be an important consideration for interpretation of data derived from a VAS. Researchers who have quantified pain perception associated with DOMS have reported that cryotherapy was effective for decreasing pain perception, which may result from a reduction in nerve conduction velocity.

**Muscle Activity**

Research evidence clearly indicates that strength decreases after DOMS has been induced. Comparison of strength before and after activity that induces DOMS may provide evidence of the effectiveness of cryotherapy for facilitation of DOMS recovery. The unique physiologic demands imposed by different sports may influence the specific parameters for cryotherapy that best facilitate recovery from DOMS. Until further research is conducted, clinicians will not have evidence to rely upon for guidance of practice.

**Functional Testing**

The adverse effects of DOMS on athletic performance can be examined using sport-specific functional tests, which may include running, jumping, throwing, and landing. Much of the previous research has analyzed single-joint movements, which may not provide an adequate representation of the effect of DOMS on sport performance capabilities.

**Summary**

Even though cryotherapy is the most common treatment for sport-related injuries, universally-accepted treatment parameters have not been established for different conditions. The effectiveness of cryotherapy for facilitation of recovery from DOMS remains unclear. Because athletes with DOMS experience negative effects for up to 72 hours postexercise, further research is needed to establish evidence-based guidelines for DOMS management.
